Acetic acid/formic acid/water (AA/FA/H₂O, 50/40/10 ratio) was used to fractionate rice straw into lignin, hemicellulosic sugars, silica and dissolving pulp. In this paper, lignin separated from rice straw was utilized in the preparation of lignin-phenol-formaldehyde resins. AA/FA/H₂O lignin was characterized as having lower molecular weight (M_w), lower methoxyl group and higher phenolic hydroxyl group, which increased its reactivity. The methoxyl group per C₉ unit was 0.87 and 0.75 for the rice straw lignin and the AA/FA/H₂O spent liquor lignin, respectively. AA/FA/H₂O lignin-phenol-formaldehyde (LPF) resins were produced in one-step preparation, with different content of lignin. The formaldehyde/phenol mole ratio (F/P) was 2.0 and the NaOH/phenol mole ratios (S/P) were between 0.3 and 0.5. The percentage of substitution of phenol by lignin was between 40 and 60%. The shear strength of plywood was tested, and the plywood bonded with LPF resin showed comparable results to those of the phenol-formaldehyde bonded plywood. The results indicated that the substitution of 50% phenol by AA/FA/H₂O lignin is feasible in the preparation of phenol-formaldehyde resin.

Keywords: organic acid lignin, methoxyl group, molecular weight, phenol-formaldehyde resin, shear strength

INTRODUCTION

Lignin is the second most abundant natural polymer, which is mostly isolated from biomass, such as wood, and agricultural residues, such as wheat straw, rice straw, bagasse *etc.* In pulping processes, lignin is dissolved in the cooking liquor. Traditionally, the black liquor lignin is burnt in pulp mills for power generation. The main challenges in using lignin for high value added products, such as chemicals and biomaterials, are its insolubility and complex polymer structure.¹ Organosolv pulping is one of the sulphur free processes to cook non-wood plants, such as grasses, with various organic acids, ethanol, methanol *etc.* As the isolated lignin will be sulphur free, it can be considered as a promising perspective for future biorefineries.²

Phenol formaldehyde (PF) resins are used as adhesive for plywood, particleboard, hardboard *etc.* However, PF resin adhesives are not used extensively in interior applications because of the high price of phenol, which is derived from petroleum. Another factor that has downcast the use of PF resin adhesives is that exposure to phenol during the processes of adhesive synthesis and plywood production can be harmful to humans. It is time to reduce the use of petroleum based products and consequently reduce greenhouse gas emission. These limitations hamper the development of the PF resin industry. Therefore, there has been growing interest in finding low-cost and nontoxic alternatives to substitute phenol.

Alternative binders for wood composite panel products have been a subject of interest for the adhesive industry for many years. Extensive research has been done on the use of lignins to prepare wood adhesives.¹⁻² However, in spite of the large body of research on lignin utilization in wood adhesives, the record of its industrial use is poor. Most research has been carried out on substituting phenol by lignin to a certain extent in phenol-formaldehyde resin (PF) preparation.³⁻⁴ Also, researchers have been trying to improve the reactivity of lignin by methylation, phenolation and co-condensation with phenol.⁵ To utilize lignin as a raw material for adhesives, two main are used: firstly, by reducing the steric hindrance by hydrolytic or oxidative depolymerization, and secondly, by phenolation, demethoxylation and methylation of lignin. The first strategy involves increasing the accessibility of the reactive sites and the second strategy involves the introduction of reactive sites.⁶ Considering the lignin monomer, an electrophilic addition between formaldehyde and free ortho positions of guaiacyl

and p-hydroxyphenyl unit may occur. Tachon *et al.*³ showed that organosolv wheat straw lignin could be used for up to 70% substitution of phenol in PF resol, without any chemical modification of lignin. The thermo-mechanical properties of the prepared resin were similar to those of the reference resin. In a study, it was observed that organic acid lignin has a high content phenolic hydroxyl groups, which facilitate reactivity in PF preparation.⁷ Recently, a biorefinery concept in dissolving pulp production from rice straw with an organic acid mixture was developed, where all the components of rice were fractionated efficiently.⁸

The main objective of this study was to use organic acid lignin from rice straw to replace part of phenol in preparing phenol formaldehyde resin and use it as binder for plywood. Organic acid and alkali lignins were characterized by FTIR, ¹H NMR, molecular weight determination, and elemental and methoxyl analyses. For comparison, the lignin isolated from rice straw by the acidic dioxane method was also characterized as mentioned above.

EXPERIMENTAL

Materials

Rice straw was collected from Mankong district. All the chemicals were reagent grade and purchased from Sigma-Aldrich.

Lignin extraction

Rice straw was ground (40/60 mesh) in a Wiley mill, extracted with acetone and dried in vacuum over P₂O₅. The acetone extract free meals were refluxed with acidic dioxane solution (9:1) (v/v). The lignin extraction method was described in detail elsewhere.⁶ The concentration of HCl in the dioxane solution was 0.2N. The dioxane to meal ratio was 8. The ground rice straw meal was refluxed with dioxane solution for about 1 hour in N₂ atm. The N₂ flow was maintained at 50 mm/min. After completing the reflux time, the wood meal dioxane mixture was filtered in a Buckner funnel using filter no. 2. The residue was washed with dioxane solution (9:1). The dioxane solution was then neutralized by adding solid Na₂CO₃ and filtered. The filtrate was concentrated in a vacuum evaporator at 40 °C. Then, the concentrated dioxane solution was added dropwise to water to precipitate lignin. The lignin precipitate was washed and dried in vacuum over P₂O₅.

Dried crude lignin was dissolved in dioxane (9:1), and again precipitated in ether with constant stirring by a magnetic bar. The precipitated pure lignin was dried in vacuum over P₂O₅ and weighed.

Rice straw delignification process

The rice straw fractionation was widely described in our previous work.⁸ 50 g of rice straw was refluxed with the mixture of formic acid, acetic acid and water under the following conditions: formic acid/acetic acid/water (FA/AA/H₂O) (V/V): 50/40/10, reaction time: 4 hours at boiling temperature, material to liquor ratio: 1:8.

Alkaline extraction of rice straw pulp

After separation of the spent liquor from the delignification step, the pulp fibres underwent the alkaline extraction process for further removal of lignin, hemicelluloses and silica.⁸ This process was carried out in a polyethylene bag with 8% sodium hydroxide at 25 °C for 2 h. The consistency was 10%. After extraction, the pulp fibres were filtered and the filtrate was collected for lignin and silica separation.

Lignin isolation from spent liquor

The lignin was dissolved during the delignification process with organic acid (AA/FA/H₂O-50/40/10). It was precipitated from the concentrated organic acid spent liquor in five volumes of water. The residue was filtered in a Buchner funnel, washed with water and vacuum-dried over P₂O₅. The isolated lignin was purified by dissolution in dioxane (9:1) and precipitation in ether, followed by vacuum drying over P₂O₅. A part of the residual lignin was dissolved during the alkaline extraction of rice straw pulp. The lignin was precipitated by reducing the pH to 2 by adding 1N HCl, which was separated by centrifugation, followed by vacuum drying over P₂O₅. The dried crude lignin was dissolved in dioxane (9:1), and again precipitated in ether with constant stirring by a magnetic bar. The precipitated pure lignin was dried in vacuum over P₂O₅ and weighed.

Lignin acetylation

An amount of 100 mg of lignin was added to 1.5 mL of dry pyridine-acetic anhydride (1:1), for 72 h. The solution was added to a 10-fold volume of ice-cold water, whereupon the acetylated sample was recovered as a precipitate, which was purified by successive washing with water and dried under vacuum over P₂O₅.

Elemental analysis

C, H, O and N analyses were carried out in the Analytical Research Division, BCSIR. The methoxyl content in dioxane lignin was determined in accordance with the Zeisel–Viebock–Schwappach method:

Methoxy group, [OCH₃] (%) = [(a*f*0.5172)/A]*100

where a – volume of 1 N Na₂S₂O₃; f – the titer factor for 0.1 N Na₂S₂O₃; 0.5172 – the quantity of OCH₃ groups, corresponding to 1 mL of 0.1 N Na₂S₂O₃; A – mg of lignin sample.

FTIR spectroscopy

Infrared spectra were recorded on a Shimadzu FTIR spectrometer model 8201PC. The dried samples were embedded in KBr pellets in a concentration of about 1 mg/100 mg KBr. The spectra were recorded in the absorption band mode in the 4000-400 cm⁻¹ range.

¹H NMR spectroscopy

The spectra of the lignin solution (100 mg of acetylated lignin contained in 0.5 mL CDCl₃) were recorded on a Bruker 400 spectrometer. The solvent was used as internal standard (ppm 7.25). For quantification of protons, the signal in specified regions of the spectrum were integrated with respect to a spectrum-wide baseline drawn at the level of the background noise, and the results were referred to the signal for methoxyl protons, whose average number per C₉ unit was established as described above.

Molecular weight

The weight average (M_w) and number average molecular (M_n) weight of acetylated dioxane, organic acid and alkali lignins were determined by GPC on a Sorex KF-802.5 column. The samples were dissolved in tetrahydrofuran (THF) and 10 μL was injected. The column was operated at 30 °C and eluted with THF at a flow rate of 1 mL/min. The column was calibrated using polystyrene standards.

Synthesis and characterization of lignin-phenol-formaldehyde resins

The LPF resins in this study were synthesized in a three-neck flask, equipped with a magnetic stirrer, cooling condenser, thermometer, and water bath.⁹ NaOH was used to catalyze the reaction in a concentration of 6% of total reactant weight. In the first step, phenol and lignin were adequately mixed, the percentage of substitution of phenol by lignin was varied between 40 and 60%. Then, the appropriate amount of NaOH solution (30% wt) was added to adjust the pH value of the mixture to 10. The NaOH/phenol mole ratio (S/P) between 0.3 to 0.5 and the formaldehyde/phenol mole ratio (F/P) was 2.0. This system was heated to 90 °C and held for 1 h. After this step, the temperature of the resulted mixture was dropped to 80 °C, and 70% of the total formaldehyde and NaOH solution (30% wt) was added. The obtained mixture was kept at 80 °C for 1 h. Next, the remaining formaldehyde was added, and the mixture was kept at 80 °C for 1 h. Finally, the temperature of the mixture was decreased to 65 °C, and the remaining NaOH solution (30% wt) and urea (5% of the total weight of phenol and lignin) was added. This resulted mixture was held at 65 °C for 0.5 h to yield the LPF resin. The pH was measured at room temperature by a Fisherbrand pH meter. Viscosity was measured by a Brookfield viscometer by different spindles at certain rpm at room temperature.

Plywood preparation and testing

Veneer was obtained from Akij Particle Board Mills Ltd., and was made from Gurjan (*Dipterocarpus turbinatus*) wood. Two layer plywoods (400 mm × 400 mm × 4.5 mm) were prepared using the LPF resin adhesives. The core veneer was coated with 140-160 g/m² adhesive on each side. The coated veneers were hot-pressed at 145 °C under 1.0 MPa for 7.0 min. The bond strength was measured according to the method described by Yang *et al.*¹⁰ in HK-10KN, Hounsefield, UK. The pH, viscosity and solid content of the adhesives were determined according to the method described by Yang *et al.*⁷

RESULTS AND DISCUSSION

Proposed process concept

A proposed biorefinery concept of dissolving pulp production from rice straw was described in our previous article,⁸ where rice straw was treated with the organic acid mixture at the boiling temperature. Most of the lignin and hemicelluloses are dissolved in spent liquor without affecting α-cellulose. Organic acid can be easily recovered from the spent liquor by evaporation. The solid residue is composed of lignin and hemicellulosic sugars (mono/oligo), which are separated by dissolving hemicelluloses in water. It was reported that organic acid spent liquor lignin from jute was characterized by high content of phenolics,⁷ which would facilitate its use in phenolic resin.^{3,11} Organic acid pulp was further treated with alkali, which dissolved more lignin, hemicelluloses and silica present in the fiber. Silica can be separated from the alkaline extracted liquor by reducing the pH. The

detailed biorefinery concept is presented in Figure 1. In this investigation, organic acid spent liquor lignin from the rice straw was used for substituting phenol in phenol-formaldehyde resin preparation.

Elemental analysis and methoxyl content

Chemical analyses and determination of methoxyl group and C₉ atoms of dioxane lignin, organic acid lignin and alkaline extracted lignin were conducted and the results are shown in Table 1. As may be noted in Table 1, the nitrogen content in dioxane lignin from rice straw was higher, compared to that of other lignins. Nitrogen was mainly derived from the protein–lignin complexes formed during delignification. A very small difference was observed in C, H, O content, but the methoxyl content decreased with treatment. In the dioxane lignin, the methoxyl content was 12.78%, which decreased to 11.53% upon acid treatment and further decreased to 9.41% upon alkaline extraction. This decrease indicated that oxidation and removal of OCH₃ occurred during AA/FA/H₂O pulping. This also suggested that the acidity of the pulping medium facilitated the loss of methoxyl groups, similarly to the case of formic acid pulping of bamboo.¹² Li *et al.*¹² also showed that the methoxyl contents in formic acid lignin were lower than that in MWL. The number of OCH₃ decreased from 1.52/C₉ in MWL to 1.29-1.32/C₉ in formic acid lignin. The C₉ formula of dioxane lignin from rice straw was C₉H_{8.56}O_{3.76}(OCH₃)_{0.87}, while for formic acid and alkali lignins it was C₉H_{8.20}O_{3.79}(OCH₃)_{0.75} and C₉H_{7.30}O_{3.55}(OCH₃)_{0.61}, respectively. Demethylation of lignin increased the reactive sites, which was beneficial for resin preparation.¹³

Fourier transform infrared (FTIR) spectroscopy

As the functional groups and chemical bonds of the dioxane and organic acid lignin samples are important to understand the chemical structure of the isolated lignins, they were investigated by FT-IR and shown in Figure 2. The characteristic absorption peaks were identified and attributed according to Faix.¹⁴

Figure 1: Organic acid based biorefinery scheme for dissolving pulp production

Table 1
Elemental analysis, methoxyl content and empirical formula of spent organic acid lignin

Lignin sample	C	H	N	O	OCH ₃	C ₉ Formula
Rice straw (dioxane)	56.34	5.31	3.1	35.25	12.78	C ₉ H _{8.56} O _{3.76} (OCH ₃) _{0.87}
Acid treated	57.86	5.17	1.01	35.96	11.53	C ₉ H _{8.20} O _{3.79} (OCH ₃) _{0.75}
Alkali treated	57.34	4.54	2.72	33.11	9.41	C ₉ H _{7.30} O _{3.55} (OCH ₃) _{0.61}

*Empirical analysis formula C_xH_yO_z(OCH₃)_n was calculated as follows: n = (%OCH₃)/31.04; x = (%C)/12 - n; y = (%H) - 3n; z = (%O)/16 - n

Figure 2: FT-IR spectra of dioxane and organic acid lignins

Both lignins exhibited a broad band at 3400 cm^{-1} , which was due to the hydroxyl groups of aromatic and aliphatic structures. The bands at 2939 and 2849 cm^{-1} are due to C-H stretching in the aromatic methoxyl group and methyl and methylene groups of the side chain. The strong band of the carbonyl group at 1720 cm^{-1} and the carbonyl group conjugated aromatic ring were found in both lignins. The bands at 1454 and 1420 cm^{-1} were attributed to the methoxyl groups, which were slightly stronger in the dioxane lignin than in the acid lignin. These results were consistent with the data on the methoxyl groups (Table 1).

Both lignins showed aromatic skeletal characteristic bands at 1600 , 1509 and 1422 cm^{-1} . C-H deformations can be found at $1454\text{--}1460\text{ cm}^{-1}$. The band at 1325 cm^{-1} is associated with the C=O stretching of the syringyl structure in lignin molecules. The peak at 1216 cm^{-1} is assigned to the guaiacyl structure in lignin molecules, which is prominent in organic acid lignin. The out-of-plane C-H bending of the syringyl content was observed at 833 cm^{-1} . The C-H stretch assigned to the syringyl rings is present at 1115 cm^{-1} in both lignins. The strong peaks at $1044\text{--}1030\text{ cm}^{-1}$ were found in both lignins, and were related to C=O stretching of primary alcohols. There was a strong band at 1357 cm^{-1} corresponding to aliphatic alcohol and aliphatic C-H in the methyl group, which was stronger in organic acid lignin, indicating that its $\beta\text{-O-4}$ and $\alpha\text{-O-4}$ linkages were cleaved, leaving a lot of non-etherified phenolic OH groups in the lignin. Organic acid delignification played an important role in the final structure of organic acid lignin. As compared to dioxane lignin, the decrease in peak intensity at 1654 cm^{-1} can be attributed to the carbonyl group stretch of conjugated p-substituted aryl ketones in organic acid lignin, indicating that this structure had been removed partly during organic acid delignification.¹⁵ Similar results were observed during kraft delignification.¹⁶

Molecular weight

The weight-average (Mw) and number-average (Mn) molecular weights and polydispersity (Mw/Mn) of the two technical lignins (organic acid and alkali lignins) and dioxane lignin from rice straw are given in Table 2. The Mw molecular weight of dioxane lignin was 10574 g/mol , while those of organic acid and alkali lignins were only 3254 and 3658 g/mol , respectively. Li *et al.*¹² also showed that formic acid lignins from bamboo had Mw ranging from 7300 to $10,020$ and Mn ranging from 3840 to 4450 , which were lower than that of MWL of bamboo. Pizzi¹⁷ suggested that high-molecular-weight lignin is beneficial in terms of synthesis time for LPF resin preparation. The addition of a high amount of lignin in the LPF synthesis disturbs the uniformity of the cured resin structure.¹⁸ The low-molecular-weight of organic acid lignin can be explained by the cleaved main internal linkages, compared with the macromolecular structure of native lignin; the cleavage introduces more active sites.

Table 2
Molecular weight of lignins

Lignin sample	Mw (g.mol ⁻¹)	Mn (g.mol ⁻¹)	Mw/Mn
Dioxane	10574	4468	2.37
Organic acid	3254	877	3.71
Alkali	3658	908	4.02

Table 3
Assignments of signals and protons per C₉ structural unit in ¹H NMR spectra of acetylated lignin

Range ppm	Main assignments	Proton per C ₉ unit		
		Dioxane	Organic acid	Alkali
7.25-6.80	Aromatic proton in guaiacyl units	0.35	0.32	0.32
6.80-6.25	Aromatic proton in syringyl units	0.46	0.50	0.36
6.25-5.75	H α of β -O-4 and β -1 structures	0.40	0.41	0.38
5.20-4.90	H of xylan residue			
4.90-4.30	H α & H β of β -O-4 structures	0.32	0.18	0.13
	H α of β - β structures			
4.30-4.00	H of xylan residue			
4.00-3.48	H of methoxyl groups	2.61	2.25	1.83
2.50-2.22	H of aromatic acetates	0.61	0.68	0.51
2.22-1.60	H of aliphatic acetates	3.01	2.17	2.00

H¹-NMR spectroscopy

The chemical structure of acetylated lignin samples of dioxane, organic acid and alkali lignins was also studied using ¹H NMR spectrometry. As pointed out in Table 3, the integral of all signals between 6.0 and 8.0 ppm can be attributed to aromatic protons in syringyl (S) and guaiacyl (G) units. Methoxyl protons (-OCH₃), closely related to the G:S proportion, give an intense signal at 3.8 ppm.

Hydroxyl groups

Acetylation produces derivatives that display broad proton signals in regions with small interference with other hydrogen signals. In addition, aromatic and aliphatic acetyl groups shifted differently (2.3 and 2.1 ppm, respectively) giving rise to separate peaks. Thus, ¹H NMR spectrometry of acetylated lignin samples reveals both the total content of acetyl groups (proportional to OH content) and the ratio between aromatic and aliphatic substituent.¹⁹

The number of free aliphatic and phenolic hydroxyl groups per C₉ unit was determined from the corresponding acetate signals. The proton of the aliphatic hydroxyl group of organic acid lignin from the spent liquor was lower and the aromatic hydroxyl group was higher than in the dioxane lignin isolated from rice straw. This result suggested that organic acid lignin would be more reactive than the original lignin from rice straw in the subsequent use in phenol formaldehyde or other resin preparation. The proton of the aliphatic and aromatic acetate group reached 3.01 and 0.61 for dioxane lignin, 2.17 and 0.68 for organic acid and 2.00 and 0.51 for alkali lignin, respectively. In a previous study, formic acid lignin showed higher ph-OH than acetic acid lignin.⁷ Sano *et al.*²⁰ observed that the content of alc-OH and ph-OH decreased with increasing the amount of acetic acid in the liquor. In proto lignin, the aliphatic hydroxyl was higher than the aromatic hydroxyl group. However, the lignin obtained from the spent liquor of formic or acetic acid had higher content of aromatic hydroxyl group than aliphatic hydroxyl group, which indicated the cleavage of β -O-4 bonds during organic acid pulping. Davis *et al.*²¹ showed that acetic acid cleaved the β -O-4 ether containing free phenolic units.

Aromatic protons

All the spectra show two peaks in the aromatic proton region, corresponding to the guaiacyl (δ 6.9) and syringyl units (δ 6.6). All the lignins showed both G and S units. The G and S type protons per C₉ unit were 0.36 and 0.46 for dioxane lignin, 0.32 and 0.50 for organic acid lignin and 0.32 and 0.36 for alkali lignin, respectively. A clear signal between 7.3 and 7.6 ppm is assigned to the aromatic protons of *p*-coumaric acid and ferulic acid, usually found in non-wood lignins, such as grass lignin.

β-O-4 structure

The aryl glycerol β-O-4 aryl ether linkage constitutes the main intermonomeric connection in lignin.¹⁹ NMR spectra show that the structural element of these lignins may contain both *erythro* and *threo* configurations due to the presence of proton at the C-α position of the side chain. The *erythro* protons (H_α) give a stronger peak at 6.01 ppm than the corresponding peak for *threo* form at δ 6.09 in all the lignins.

Lignin-phenol-formaldehyde (LPF)

Figure 3 presents the proposed reaction during the synthesis of the resin. NaOH acts as catalyst, which facilitates the condensation reaction by activating the lignin hydroxyl group to link with the formaldehyde. Having lower methoxyl content per C₉ unit and lower molecular weight, the organic acid treated rice straw lignin had more active sites to react with formaldehyde and eventually form crosslinks with urea as well.

The prepared LPF resin adhesives using organic acid lignin were dark-brown aqueous solutions with satisfactory water solubility. As shown in Table 4, the viscosity increased with the addition of lignin, which can be explained by the colloidal nature of the high-molecular-weight lignin in alkaline solution. The viscosity of LPF resin adhesives was similar to that obtained for biorefinery technical lignin and higher than that of the commercial phenol-formaldehyde resin adhesive.⁷ Highly viscous resin products can be difficult to effectively utilize in the plywood industry. As the prepared LPF resin was soluble in water, so the viscosity can be readily adjustable. The addition of lignin increased the solid content of the prepared resin. Higher solid content may facilitate the formation of a continuous bond line between the two cementing limiting surfaces. Another important parameter of phenol formaldehyde resin is the alkaline pH range – the pH of our final resin was kept around 10.5. An earlier research showed that the presence of alkali increases the hygroscopicity and enhances the time dependent creep of PF resins due to the plasticisation of the adhesive. The PF resins with a high pH have great potential to develop delayed elastic creep.²²

The shear strength values of the plywood bonded using LPF resin adhesives are presented in Table 4. Plywood specimens were attached to each other using the adhesives and hot pressed at 145 °C for curing. During curing, the crosslinking occurred among the active functional groups of lignin, formaldehyde and urea.

Figure 3: Proposed crosslinked structure of LPF

Table 4
Performance of lignin substitution in phenol-formaldehyde resin

Lignin substitution (%)	pH	Solid content	Viscosity (mPa.s)	Shear strength (MPa)
0	11.06	45.33	1356	8.37
40	10.65	48.91	1824	8.02
50	10.32	50.06	1890	7.99
60	10.06	51.43	1956	7.81

It was observed that the strength of our prepared resin was almost similar to that of the PF resin, which indicated that the organic acid lignin was similarly reactive to phenol, due to its lower Mw. Moreover, the addition of urea in the resin preparation accelerated the crosslinking reactions, forming additional structures and a complex composition, which led the final resin with such strength. Evidence has been found of the forming Ph-CH₂-Urea linkages during phenol-urea-formaldehyde resin synthesis.²³ Similarly, Zhang *et al.*²⁴ crosslinked corn stalk lignin with furfuryl alcohol-formaldehyde (FF) resin in the laboratory and produced good quality lignin-furfuryl-formaldehyde (LFF) resin. The -CH(OH)- groups were involved in the crosslinking of the LFF adhesive.

Many studies on preparing lignin based phenol formaldehyde resins have been carried out. However, most of the resins were prepared from kraft lignin or soda lignin, which had a high number average molecular weight and less active sites to react with formaldehyde. In contrast, in this research work, after fractionating the rice straw with a mixture of organic acid, we attempted to utilize the lower molecular weight acid lignin. A lignin based phenol-urea-formaldehyde resin was produced and applied to bond plywood specimens, leading to satisfactory tensile strength, compared to that achieved using commercial phenol-formaldehyde resin.

CONCLUSION

Organic acid allows efficient fractionation of rice straw into its components. Fractionated organic acid lignin had lower methoxyl content and higher phenolic hydroxyl content, as compared to the original rice straw lignin, which subsequently helped out in replacing phenol in phenol-formaldehyde resin preparation. Organic acid lignin was characterized as having lower molecular weight and higher polydispersity. The G and S type protons per C₉ unit were 0.36 and 0.46 for dioxane lignin, and 0.32 and 0.50 for organic acid lignin. Phenol was replaced by organic acid lignin in LPF resin preparation and the prepared LPF was used to bond plywood. The shear strength of the plywood bonded using LPF resin adhesives was almost similar that achieved in the case of PF resin, which indicated that the organic acid lignin was similarly reactive to phenol.

ACKNOWLEDGEMENT: Authors wish to thank the Ministry of Science and Technology, Bangladesh Government, BCSIR and University Grant Commission of Bangladesh, for financial assistance in carrying out the research.
